Sound Synthesizer Creates New Musical Effects

Well-known electronic circuits are used in system combinations so that unconventional sounds and patterns can be produced from ordinary audio. For example, a singer can generate his own string bass accompaniment simultaneously with his voice.

NEW FRONTIERS IN ELECTRONIC MUSIC

Music is the art of making pleasing, expressive or intelligible combinations of sounds and making such combinations into compositions of definite structure and significance according to the laws of melody harmony and rhythm. It is also the art of inventing, writing or rendering such compositions, whether vocal or instrumental.

Ancient Greek music was limited in expression by the primitive instruments used, mostly of the lyre and flute types. However, it did establish the diatonic scales based on the tetrachord as a unit and gave us the rudiments of key relationships.

Early church music gave us the neumes to indicate pitch, the development of staff notation, and the superceding of the tetrachord unit by the hexachord. The practice of descent, or simultaneous melody, gave rise to mensurable music which in turn gave birth to counterpoint.

Establishment of modern major and minor scales with the octave as a unit and of equal temperament made possible modulation into any key and led to the development of harmony.

Great improvements in instrument making marked the growth of purely instrumental music. The modern symphony originated in the time of Haydn and others about 1770.

Recently, increasingly dissonant linear counterpoint, Schoenberg as an example, is becoming popular. The French gave us polytonality and the Russian composers have given us barbaric, dynamic rhythms while American jazz has contributed to the music of the dynamic era in which we live.

Modern proponents of musical thought and expression have often complained of being musically restricted by instrument range and
modulator shown in Fig. 1A yields the sum and differences of the frequencies applied to its two inputs but contains neither input frequency. This feature has been used to create new sounds and effects. Figure 1B shows a tone applied to input 1 and a group of harmonically related frequencies applied to input 2. The output spectrum is shown in Fig. 1C.

Due to operation of the ring-bridge modulator, the output frequencies are no longer harmonically related to each other. If a group of properly related frequencies were applied to both inputs and a percussive-type envelope were applied to the output signal, a bell-like tone would be produced.

In a more general presentation, the curves of Fig. 2 show the variety of tone spectra that may be derived with a gliding frequency between 1 cps and 10 Kc applied to one and two fixed 440 and 880 cps frequencies (in octave relationship) applied to the other input of the ring-bridge modulator. The output frequencies are identified on the graph.

Frequencies applied to the ring-bridge modulator inputs are not limited to the audio range. Application of a subsonic frequency to one input will periodically modulate a frequency applied to the other. Application of white noise to one input and a single audio frequency to the other input will yield tuned noise at the output. Application of a percussive envelope to one input simultaneously with a steady tone at the other input will result in a percussive-type output that will have the characteristics of the steady tone modulated by the percussive envelope.

The unit shown in Fig. 3 provides congruent envelope shaping as well as the coincident percussive envelope shaping of the program material. One input accepts the control signal while the other input accepts the material to be subjected to envelope shaping. The processed audio appears at the output of the gating circuit.

To derive control voltages for the gating functions, the audio at the control input is amplified, rectified and applied to a low-pass filter. Thus, a relatively ripple-free variable d-c bias will actuate the variable-gain, push-pull amplifier gate. When switch S1 is in the gating position, the envelope of the control signal shapes that of the program material.

To prevent the delay caused by C1 and C2 on fast-changing control voltages, and to eliminate asymmetry caused by the different output impedances at the plate and cathode of V1, relatively high-value resistors R1 and R2 are inserted between phase inverter V1 and the push-pull output of the gate circuit. These resistors are of the same order of magnitude as biasing resistors R1 and R2 to secure a balance between the control d-c signal and the audio portion of the program material.

The input circuits of V1 and V2...

act as a high-pass filter. The cut-off frequency of these filters exceeds that of the ripple filter by such an amount that no disturbing audio frequency from the control input will feed through to the gate. This is important for clean operation of the percussive envelope circuit. The pulses that initiate the percussive envelopes are generated by Schmitt trigger V1 and V2. Positive-going output pulses charge C1 (or C2 or C3, chosen by S3) with the discharge through R8. The time constant depends on the position of S3.

To make the trigger circuit respond to the beginning of a signal as well as to signal growth, differentiator C2 and Rs plus Rs is used at the input of V1. The response to signal growth is especially useful in causing the system to yield to a crescendo in a music passage or to instants of accentuation in the flow of speech frequencies.

The practical application of the audio-controlled percussion device within a system for the production of new musical effects is shown in Fig. 4. The sound of a bongo drum triggers the percussion circuit, which in turn converts the sustained chords played by the organ into percussive tones. The output signal is applied to a tape-loop repetition unit that has four equally spaced heads, one for record and three for playback. By connecting the record head and playback head 2 in parallel, output A is produced. By connecting playback head 1 and playback head 3 in parallel, output B is produced, and a distinctive ABAB pattern may be achieved. Outputs A and B can be connected

**FIG. 4**—Organ chords are given drum envelope to produce musical drum effect. Other instruments, including voice, may be substituted for the organ.
to formant filters having different resonance frequencies.

The number of repetitions may be extended if a feedback loop is inserted between playback head 2 and the record amplifier. The output voltages of the two filters and the microphone preamplifier are applied to a mixer in which the ratio of drum sound to modified percussion organ sound may be controlled.

A presentation dealing more specifically with the tape-loop device and the sound-processing modules used in the synthesizer is shown in Fig. 5.

The program material originating from the melody instrument is applied to one of the inputs of the audio-controlled gate and percussion unit. There it is gated by the audio from a percussion instrument. The percussive melody sounds at the output of the gate are applied to the tape-loop repetition system. Output signal A—the direct signal and the information from playback head 2—is applied through amplifier A and filter 1 to the mixer. Output signal B—the signals from playback heads 1 and 3—is applied through amplifier B to one input of the ring-bridge modulator. The other ring-bridge modulator input is connected to the output of an audio signal generator.

The mixed and frequency converted signal at the output of the ring-bridge modulator is applied through filter 2 to the mixer. At the mixer output a percussive ABAB signal (stemming from a single melody note, triggered by a single drum signal) is obtained. In its A portion it has the original melody instrument pitch while its B portion is the converted nonharmonic overtone structure, both affected by the different voicings of the two filters. When the direct drum signal is applied to a third mixer input, the output will sound like a voiced drum with an intricate after sound. The repetition of the ABAB pattern may be extended by a feedback loop between playback head 2 and the record amplifier.

When applying the human singing voice to the input of the fundamental frequency selector, the extracted fundamental pitch may be distorted in the squaring circuit and applied to the frequency divider (or dividers). This will derive a melody line whose pitch will be one octave lower than that of the singer. The output of the frequency divider may then be applied through a voicing filter to the program input of the audio-controlled gate and percussion unit. The control input of this circuit may be actuated by the original singing voice, after having passed through a low-pass filter of such a cutoff frequency that only vowels—typical for syllables—would trigger the circuit. At the output of the audio-controlled gate, percussive sounds with the voice of a string bass will be obtained mixed with the original voice of the singer. The human voice output signal will now be accompanied by a coincident string bass sound which may be further processed in the tape-loop repetition unit.

The arbitrarily selected electronic modules of this synthesizer are of a limited variety and could be supplemented by other modules.

A system synthesizer may find many applications such as exploration of new types of electronic music or as a tool for composers who are searching for novel sounds and musical effects. Such a device will present a challenge to the imagination of composer-programmer.

The modern approach of synthesizing intricate electronic systems from modules with a limited number of basic functions has proven successful in the computer field. This approach has now been made in the area of sound synthesis.

With means for compiling any desired modular configuration, an audio system synthesizer could become a flexible and versatile tool for sound processing and would be suited to meet the evergrowing demand for exploration and production of new sounds.
